```

2 Overview

Markov chains are one of the most useful classes of stochastic processes, being

- simple, flexible and supported by many elegant theoretical results
- valuable for building intuition about random dynamic models
- central to quantitative modeling in their own right
You will find them in many of the workhorse models of economics and finance

In this lecture, we review some of the theory of Markov chains

We will also introduce some of the high-quality routines for working with Markov chains available in QuantEcon.py

Prerequisite knowledge is basic probability and linear algebra

3 Definitions

The following concepts are fundamental

3.1 Stochastic Matrices

A stochastic matrix (or Markov matrix) is an \( n \times n \) square matrix \( P \) such that

1. each element of \( P \) is nonnegative, and
2. each row of \( P \) sums to one

Each row of \( P \) can be regarded as a probability mass function over \( n \) possible outcomes

It is too not difficult to check [1] that if \( P \) is a stochastic matrix, then so is the \( k \)-th power \( P^k \) for all \( k \in \mathbb{N} \)

3.2 Markov Chains

There is a close connection between stochastic matrices and Markov chains

To begin, let \( S \) be a finite set with \( n \) elements \( \{x_1, \ldots, x_n\} \)

The set \( S \) is called the \textbf{state space} and \( x_1, \ldots, x_n \) are the \textbf{state values}

A Markov chain \( \{X_t\} \) on \( S \) is a sequence of random variables on \( S \) that have the \textbf{Markov property}

This means that, for any date \( t \) and any state \( y \in S \),

\[
P\{X_{t+1} = y \mid X_t \} = P\{X_{t+1} = y \mid X_t, X_{t-1}, \ldots\}
\]

(1)

In other words, knowing the current state is enough to know probabilities for future states

In particular, the dynamics of a Markov chain are fully determined by the set of values

\[
P(x, y) := P\{X_{t+1} = y \mid X_t = x\} \quad (x, y \in S)
\]

(2)

By construction,

- \( P(x, y) \) is the probability of going from \( x \) to \( y \) in one unit of time (one step)
- \( P(x, \cdot) \) is the conditional distribution of \( X_{t+1} \) given \( X_t = x \)
We can view $P$ as a stochastic matrix where

$$P_{ij} = P(x_i, x_j) \quad 1 \leq i, j \leq n$$

Going the other way, if we take a stochastic matrix $P$, we can generate a Markov chain $\{X_t\}$ as follows:

- draw $X_0$ from some specified distribution
- for each $t = 0, 1, \ldots$, draw $X_{t+1}$ from $P(X_t, \cdot)$

By construction, the resulting process satisfies Eq. (2)

### 3.3 Example 1

Consider a worker who, at any given time $t$, is either unemployed (state 0) or employed (state 1).

Suppose that, over a one month period,

1. An unemployed worker finds a job with probability $\alpha \in (0, 1)$
2. An employed worker loses her job and becomes unemployed with probability $\beta \in (0, 1)$

In terms of a Markov model, we have

- $S = \{0, 1\}$
- $P(0, 1) = \alpha$ and $P(1, 0) = \beta$

We can write out the transition probabilities in matrix form as

$$P = \begin{pmatrix}
1 - \alpha & \alpha \\
\beta & 1 - \beta
\end{pmatrix}$$

Once we have the values $\alpha$ and $\beta$, we can address a range of questions, such as

- What is the average duration of unemployment?
- Over the long-run, what fraction of time does a worker find herself unemployed?
- Conditional on employment, what is the probability of becoming unemployed at least once over the next 12 months?

We’ll cover such applications below

### 3.4 Example 2

$$P = \begin{pmatrix}
0.971 & 0.029 & 0 \\
0.145 & 0.778 & 0.077 \\
0 & 0.508 & 0.492
\end{pmatrix}$$

where
• the frequency is monthly
• the first state represents “normal growth”
• the second state represents “mild recession”
• the third state represents “severe recession”

For example, the matrix tells us that when the state is normal growth, the state will again be normal growth next month with probability 0.97

In general, large values on the main diagonal indicate persistence in the process \( \{X_t\} \)

This Markov process can also be represented as a directed graph, with edges labeled by transition probabilities

Here “ng” is normal growth, “mr” is mild recession, etc.

4 Simulation

One natural way to answer questions about Markov chains is to simulate them

(To approximate the probability of event \( E \), we can simulate many times and count the fraction of times that \( E \) occurs)

Nice functionality for simulating Markov chains exists in QuantEcon.py

• Efficient, bundled with lots of other useful routines for handling Markov chains

However, it’s also a good exercise to roll our own routines — let’s do that first and then come back to the methods in QuantEcon.py

In these exercises, we’ll take the state space to be \( S = 0, \ldots, n - 1 \)

4.1 Rolling Our Own

To simulate a Markov chain, we need its stochastic matrix \( P \) and either an initial state or a probability distribution \( \psi \) for initial state to be drawn from

The Markov chain is then constructed as discussed above. To repeat:

1. At time \( t = 0 \), the \( X_0 \) is set to some fixed state or chosen from \( \psi \)
2. At each subsequent time \( t \), the new state \( X_{t+1} \) is drawn from \( P(X_t, \cdot) \)

In order to implement this simulation procedure, we need a method for generating draws from a discrete distribution

For this task, we’ll use DiscreteRV from QuantEcon
In [2]: import quantecon as qe
   import numpy as np

    ψ = (0.1, 0.9)  # Probabilities over sample space {0, 1}
cdf = np.cumsum(ψ)
qe.random.draw(cdf, 5)  # Generate 5 independent draws from ψ

Out[2]: array([1, 1, 1, 1, 1])

We’ll write our code as a function that takes the following three arguments

- A stochastic matrix $P$
- An initial state $init$
- A positive integer $sample_size$ representing the length of the time series the function should return

In [3]: def mc_sample_path(P, init=0, sample_size=1000):
    # === make sure P is a NumPy array ===#
    P = np.asarray(P)
    # === allocate memory ===#
    X = np.empty(sample_size, dtype=int)
    X[0] = init
    # === convert each row of P into a distribution ===#
    # In particular, $P_{dist}[i] = \text{the distribution corresponding to } P[i, :]$
    n = len(P)
    P_dist = [np.cumsum(P[i, :]) for i in range(n)]
    # === generate the sample path ===#
    for t in range(sample_size - 1):
        X[t+1] = qe.random.draw(P_dist[X[t]])
    return X

Let’s see how it works using the small matrix

$$
P := \begin{pmatrix}
0.4 & 0.6 \\
0.2 & 0.8 \\
\end{pmatrix}
$$

As we’ll see later, for a long series drawn from $P$, the fraction of the sample that takes value 0 will be about 0.25

If you run the following code you should get roughly that answer

In [4]: P = [[0.4, 0.6], [0.2, 0.8]]
   X = mc_sample_path(P, sample_size=100000)
   np.mean(X == 0)

Out[4]: 0.25109

4.2 Using QuantEcon’s Routines

As discussed above, QuantEcon.py has routines for handling Markov chains, including simulation

Here’s an illustration using the same $P$ as the preceding example

In [5]: P = [[0.4, 0.6], [0.2, 0.8]]
   mc = qe.MarkovChain(P)
   X = mc.simulate(ts_length=1000000)
   np.mean(X == 0)
In fact the QuantEcon.py routine is JIT compiled and much faster
(Because it’s JIT compiled the first run takes a bit longer — the function has to be compiled and stored in memory)

```python
In [6]: %timeit mc_sample_path(P, sample_size=1000000) # our version
678 ms ± 9.12 ms per loop (mean ± std. dev. of 7 runs, 1 loop each)
```

```python
In [7]: %timeit mc.simulate(ts_length=1000000) # qe version
30.2 ms ± 396 µs per loop (mean ± std. dev. of 7 runs, 10 loops each)
```

### Adding State Values and Initial Conditions

If we wish to, we can provide a specification of state values to MarkovChain

These state values can be integers, floats, or even strings

The following code illustrates

```python
In [8]: mc = qe.MarkovChain(P, state_values=('unemployed', 'employed'))
   mc.simulate(ts_length=4, init='employed')
Out[8]: array(['employed', 'employed', 'employed', 'employed'], dtype='<U10')
```

```python
In [9]: mc.simulate(ts_length=4, init='unemployed')
Out[9]: array(['unemployed', 'employed', 'employed', 'employed'], dtype='<U10')
```

```python
In [10]: mc.simulate(ts_length=4)  # Start at randomly chosen initial state
Out[10]: array([1, 1, 1, 1])
```

If we want to simulate with output as indices rather than state values we can use

```python
In [11]: mc.simulate_indices(ts_length=4)
Out[11]: array([1, 1, 1, 1])
```

### 5 Marginal Distributions

Suppose that

1. \( \{X_t\} \) is a Markov chain with stochastic matrix \( P \)
2. the distribution of \( X_t \) is known to be \( \psi_t \)

What then is the distribution of \( X_{t+1} \), or, more generally, of \( X_{t+m} \)?
5.1 Solution

Let $\psi_t$ be the distribution of $X_t$ for $t = 0, 1, 2, ...$

Our first aim is to find $\psi_{t+1}$ given $\psi_t$ and $P$

To begin, pick any $y \in S$

Using the law of total probability, we can decompose the probability that $X_{t+1} = y$ as follows:

$$P\{X_{t+1} = y\} = \sum_{x \in S} P\{X_{t+1} = y \mid X_t = x\} \cdot P\{X_t = x\}$$

In words, to get the probability of being at $y$ tomorrow, we account for all ways this can happen and sum their probabilities.

Rewriting this statement in terms of marginal and conditional probabilities gives:

$$\psi_{t+1}(y) = \sum_{x \in S} P(x, y) \psi_t(x)$$

There are $n$ such equations, one for each $y \in S$

If we think of $\psi_{t+1}$ and $\psi_t$ as row vectors (as is traditional in this literature), these $n$ equations are summarized by the matrix expression

$$\psi_{t+1} = \psi_t P$$

In other words, to move the distribution forward one unit of time, we postmultiply by $P$

By repeating this $m$ times we move forward $m$ steps into the future.

Hence, iterating on Eq. (4), the expression $\psi_{t+m} = \psi_t P^m$ is also valid — here $P^m$ is the $m$-th power of $P$

As a special case, we see that if $\psi_0$ is the initial distribution from which $X_0$ is drawn, then $\psi_0 P^m$ is the distribution of $X_m$

This is very important, so let’s repeat it

$$X_0 \sim \psi_0 \implies X_m \sim \psi_0 P^m \quad (5)$$

and, more generally,

$$X_t \sim \psi_t \implies X_{t+m} \sim \psi_t P^m \quad (6)$$

5.2 Multiple Step Transition Probabilities

We know that the probability of transitioning from $x$ to $y$ in one step is $P(x, y)$

It turns out that the probability of transitioning from $x$ to $y$ in $m$ steps is $P^m(x, y)$, the $(x, y)$-th element of the $m$-th power of $P$

To see why, consider again Eq. (6), but now with $\psi_t$ putting all probability on state $x$
• 1 in the $x$-th position and zero elsewhere

Inserting this into Eq. (6), we see that, conditional on $X_t = x$, the distribution of $X_{t+m}$ is the $x$-th row of $P^m$

In particular

$$P\{X_{t+m} = y\} = P^m(x, y) = (x, y)\text{-th element of } P^m$$

5.3 Example: Probability of Recession

Recall the stochastic matrix $P$ for recession and growth considered above

Suppose that the current state is unknown — perhaps statistics are available only at the end of the current month

We estimate the probability that the economy is in state $x$ to be $\psi(x)$

The probability of being in recession (either mild or severe) in 6 months time is given by the inner product

$$\psi P^6 \cdot \begin{pmatrix} 0 \\ 1 \\ 1 \end{pmatrix}$$

5.4 Example 2: Cross-Sectional Distributions

The marginal distributions we have been studying can be viewed either as probabilities or as cross-sectional frequencies in large samples

To illustrate, recall our model of employment/unemployment dynamics for a given worker discussed above

Consider a large (i.e., tending to infinite) population of workers, each of whose lifetime experience is described by the specified dynamics, independent of one another

Let $\psi$ be the current cross-sectional distribution over $\{0, 1\}$

• For example, $\psi(0)$ is the unemployment rate

The cross-sectional distribution records the fractions of workers employed and unemployed at a given moment

The same distribution also describes the fractions of a particular worker’s career spent being employed and unemployed, respectively

6 Irreducibility and Aperiodicity

Irreducibility and aperiodicity are central concepts of modern Markov chain theory

Let’s see what they’re about
6.1 Irreducibility

Let $P$ be a fixed stochastic matrix

Two states $x$ and $y$ are said to communicate with each other if there exist positive integers $j$ and $k$ such that

$$P^j(x, y) > 0 \quad \text{and} \quad P^k(y, x) > 0$$

In view of our discussion above, this means precisely that

- state $x$ can be reached eventually from state $y$, and
- state $y$ can be reached eventually from state $x$

The stochastic matrix $P$ is called irreducible if all states communicate; that is, if $x$ and $y$ communicate for all $(x, y)$ in $S \times S$

For example, consider the following transition probabilities for wealth of a fictitious set of households

We can translate this into a stochastic matrix, putting zeros where there’s no edge between nodes

$$P := \begin{pmatrix}
0.9 & 0.1 & 0 \\
0.4 & 0.4 & 0.2 \\
0.1 & 0.1 & 0.8
\end{pmatrix}$$

It’s clear from the graph that this stochastic matrix is irreducible: we can reach any state from any other state eventually

We can also test this using QuantEcon.py’s MarkovChain class

```
In [12]: P = [[0.9, 0.1, 0.0], [0.4, 0.4, 0.2], [0.1, 0.1, 0.8]]
mc = qe.MarkovChain(P, ('poor', 'middle', 'rich'))
mc.is_irreducible
```

Out[12]: True

Here’s a more pessimistic scenario, where the poor are poor forever
This stochastic matrix is not irreducible, since, for example, rich is not accessible from poor.

Let's confirm this:

```python
In [13]: P = [[1.0, 0.0, 0.0],
       [0.1, 0.8, 0.1],
       [0.0, 0.2, 0.8]]
mc = qe.MarkovChain(P, ('poor', 'middle', 'rich'))
mc.is_irreducible
```

```
Out[13]: False
```

We can also determine the “communication classes”:

```python
In [14]: mc.communication_classes
```

```
Out[14]: [array(['poor'], dtype='<U6'), array(['middle', 'rich'], dtype='<U6')]
```

It might be clear to you already that irreducibility is going to be important in terms of long run outcomes.

For example, poverty is a life sentence in the second graph but not the first.

We'll come back to this a bit later.

### 6.2 Aperiodicity

Loosely speaking, a Markov chain is called periodic if it cycles in a predictable way, and aperiodic otherwise.

Here's a trivial example with three states:

The chain cycles with period 3:
More formally, the **period** of a state $x$ is the greatest common divisor of the set of integers $D(x) := \{j \geq 1 : P^j(x,x) > 0\}$

In the last example, $D(x) = \{3, 6, 9, \ldots\}$ for every state $x$, so the period is 3

A stochastic matrix is called **aperiodic** if the period of every state is 1, and **periodic** otherwise

For example, the stochastic matrix associated with the transition probabilities below is periodic because, for example, state $a$ has period 2

```
In [15]: P = [[0.0, 1.0, 0.0],
           [0.5, 0.0, 0.5],
           [0.5, 0.5, 0.0]]
mc = qe.MarkovChain(P)
mc.period
```

```
Out[15]: 3
```

7 Stationary Distributions

As seen in Eq. (4), we can shift probabilities forward one unit of time via postmultiplication by $P$

Some distributions are invariant under this updating process — for example,

```
In [18]: P = np.array([[.4, .6], [.2, .8]])
ψ = (0.25, 0.75)
ψ @ P
```

```
Out[18]: array([0.25, 0.75])
```

Such distributions are called **stationary**, or **invariant**

Formally, a distribution $\psi^*$ on $S$ is called **stationary** for $P$ if $\psi^* = \psi^* P$
From this equality, we immediately get $\psi^* = \psi^* P^t$ for all $t$

This tells us an important fact: If the distribution of $X_0$ is a stationary distribution, then $X_t$ will have this same distribution for all $t$

Hence stationary distributions have a natural interpretation as stochastic steady states — we’ll discuss this more in just a moment

Mathematically, a stationary distribution is a fixed point of $P$ when $P$ is thought of as the map $\psi \mapsto \psi P$ from (row) vectors to (row) vectors

**Theorem.** Every stochastic matrix $P$ has at least one stationary distribution

(We are assuming here that the state space $S$ is finite; if not more assumptions are required)

For proof of this result, you can apply Brouwer’s fixed point theorem, or see EDTC, theorem 4.3.5

There may in fact be many stationary distributions corresponding to a given stochastic matrix $P$

- For example, if $P$ is the identity matrix, then all distributions are stationary

Since stationary distributions are long run equilibria, to get uniqueness we require that initial conditions are not infinitely persistent

Infinite persistence of initial conditions occurs if certain regions of the state space cannot be accessed from other regions, which is the opposite of irreducibility

This gives some intuition for the following fundamental theorem

**Theorem.** If $P$ is both aperiodic and irreducible, then

1. $P$ has exactly one stationary distribution $\psi^*$
2. For any initial distribution $\psi_0$, we have $\|\psi_0 P^t - \psi^*\| \to 0$ as $t \to \infty$

For a proof, see, for example, theorem 5.2 of [2]

(Note that part 1 of the theorem requires only irreducibility, whereas part 2 requires both irreducibility and aperiodicity)

A stochastic matrix satisfying the conditions of the theorem is sometimes called **uniformly ergodic**

One easy sufficient condition for aperiodicity and irreducibility is that every element of $P$ is strictly positive

- Try to convince yourself of this

**7.1 Example**

Recall our model of employment/unemployment dynamics for a given worker discussed above

Assuming $\alpha \in (0, 1)$ and $\beta \in (0, 1)$, the uniform ergodicity condition is satisfied

Let $\psi^* = (p, 1 - p)$ be the stationary distribution, so that $p$ corresponds to unemployment (state 0)
Using $\psi^* = \psi^* P$ and a bit of algebra yields

$$p = \frac{\beta}{\alpha + \beta}$$

This is, in some sense, a steady state probability of unemployment — more on interpretation below.

Not surprisingly it tends to zero as $\beta \to 0$, and to one as $\alpha \to 0$

### 7.2 Calculating Stationary Distributions

As discussed above, a given Markov matrix $P$ can have many stationary distributions. That is, there can be many row vectors $\psi$ such that $\psi = \psi P$.

In fact if $P$ has two distinct stationary distributions $\psi_1, \psi_2$ then it has infinitely many, since in this case, as you can verify,

$$\psi_3 := \lambda \psi_1 + (1 - \lambda) \psi_2$$

is a stationary distribution for $P$ for any $\lambda \in [0, 1]$.

If we restrict attention to the case where only one stationary distribution exists, one option for finding it is to try to solve the linear system $\psi (I_n - P) = 0$ for $\psi$, where $I_n$ is the $n \times n$ identity.

But the zero vector solves this equation.

Hence we need to impose the restriction that the solution must be a probability distribution.

A suitable algorithm is implemented in QuantEcon.py — the next code block illustrates.

```python
In [19]: P = [[0.4, 0.6], [0.2, 0.8]]
mc = qe.MarkovChain(P)
mc.stationary_distributions  # Show all stationary distributions

Out[19]: array([[0.25, 0.75]])
```

The stationary distribution is unique.

### 7.3 Convergence to Stationarity

Part 2 of the Markov chain convergence theorem stated above tells us that the distribution of $X_t$ converges to the stationary distribution regardless of where we start off.

This adds considerable weight to our interpretation of $\psi^*$ as a stochastic steady state.

The convergence in the theorem is illustrated in the next figure.

```python
In [20]: from mpl_toolkits.mplot3d import Axes3D
    import matplotlib.pyplot as plt
    %matplotlib inline
P = ((0.971, 0.029, 0.000),
     (0.145, 0.778, 0.077),
     )
```
Here

- $P$ is the stochastic matrix for recession and growth considered above
- The highest red dot is an arbitrarily chosen initial probability distribution $\psi$, represented as a vector in $\mathbb{R}^3$
• The other red dots are the distributions $\psi P^t$ for $t = 1, 2, ...$
• The black dot is $\psi^*$

The code for the figure can be found here — you might like to try experimenting with different initial conditions

8 Ergodicity

Under irreducibility, yet another important result obtains: For all $x \in S$, 

$$\frac{1}{n} \sum_{t=1}^{m} 1\{X_t = x\} \to \psi^*(x) \quad \text{as} \quad m \to \infty \tag{7}$$

Here

• $1\{X_t = x\} = 1$ if $X_t = x$ and zero otherwise
• convergence is with probability one
• the result does not depend on the distribution (or value) of $X_0$

The result tells us that the fraction of time the chain spends at state $x$ converges to $\psi^*(x)$ as time goes to infinity

This gives us another way to interpret the stationary distribution — provided that the convergence result in Eq. (7) is valid

The convergence in Eq. (7) is a special case of a law of large numbers result for Markov chains — see EDTC, section 4.3.4 for some additional information

8.1 Example

Recall our cross-sectional interpretation of the employment/unemployment model discussed above

Assume that $\alpha \in (0, 1)$ and $\beta \in (0, 1)$, so that irreducibility and aperiodicity both hold

We saw that the stationary distribution is $(p, 1 - p)$, where

$$p = \frac{\beta}{\alpha + \beta}$$

In the cross-sectional interpretation, this is the fraction of people unemployed

In view of our latest (ergodicity) result, it is also the fraction of time that a worker can expect to spend unemployed

Thus, in the long-run, cross-sectional averages for a population and time-series averages for a given person coincide

This is one interpretation of the notion of ergodicity
We are interested in computing expectations of the form
\[ \mathbb{E}[h(X_t)] \tag{8} \]
and conditional expectations such as
\[ \mathbb{E}[h(X_{t+k}) \mid X_t = x] \tag{9} \]
where

- \( \{X_t\} \) is a Markov chain generated by \( n \times n \) stochastic matrix \( P \)
- \( h \) is a given function, which, in expressions involving matrix algebra, we’ll think of as the column vector

\[ h = \begin{pmatrix} h(x_1) \\ \vdots \\ h(x_n) \end{pmatrix} \]

The unconditional expectation Eq. (8) is easy: We just sum over the distribution of \( X_t \) to get
\[ \mathbb{E}[h(X_t)] = \sum_{x \in S} (\psi P^t)(x) h(x) \]
Here \( \psi \) is the distribution of \( X_0 \)

Since \( \psi \) and hence \( \psi P^t \) are row vectors, we can also write this as
\[ \mathbb{E}[h(X_t)] = \psi P^t h \]

For the conditional expectation Eq. (9), we need to sum over the conditional distribution of \( X_{t+k} \) given \( X_t = x \)

We already know that this is \( P^k(x, \cdot) \), so
\[ \mathbb{E}[h(X_{t+k}) \mid X_t = x] = (P^k h)(x) \tag{10} \]

The vector \( P^k h \) stores the conditional expectation \( \mathbb{E}[h(X_{t+k}) \mid X_t = x] \) over all \( x \)

### 9.1 Expectations of Geometric Sums

Sometimes we also want to compute expectations of a geometric sum, such as \( \sum_{t=0}^{\infty} \beta^t h(X_t) \)

In view of the preceding discussion, this is
\[ \mathbb{E} \left[ \sum_{j=0}^{\infty} \beta^j h(X_{t+j}) \mid X_t = x \right] = [(I - \beta P)^{-1} h](x) \]
where

\[(I - \beta P)^{-1} = I + \beta P + \beta^2 P^2 + \ldots\]

Premultiplication by \((I - \beta P)^{-1}\) amounts to “applying the resolvent operator”

10 Exercises

10.1 Exercise 1

According to the discussion above, if a worker’s employment dynamics obey the stochastic matrix

\[P = \begin{pmatrix} 1 - \alpha & \alpha \\ \beta & 1 - \beta \end{pmatrix}\]

with \(\alpha \in (0, 1)\) and \(\beta \in (0, 1)\), then, in the long-run, the fraction of time spent unemployed will be

\[p := \frac{\beta}{\alpha + \beta}\]

In other words, if \(\{X_t\}\) represents the Markov chain for employment, then \(X_m \to p\) as \(m \to \infty\), where

\[\bar{X}_m := \frac{1}{m} \sum_{t=1}^{m} 1\{X_t = 0\}\]

Your exercise is to illustrate this convergence

First,

- generate one simulated time series \(\{X_t\}\) of length 10,000, starting at \(X_0 = 0\)
- plot \(\bar{X}_m - p\) against \(m\), where \(p\) is as defined above

Second, repeat the first step, but this time taking \(X_0 = 1\)

In both cases, set \(\alpha = \beta = 0.1\)

The result should look something like the following — modulo randomness, of course
A topic of interest for economics and many other disciplines is *ranking*

Let’s now consider one of the most practical and important ranking problems — the rank assigned to web pages by search engines

(Although the problem is motivated from outside of economics, there is in fact a deep connection between search ranking systems and prices in certain competitive equilibria — see [1])

To understand the issue, consider the set of results returned by a query to a web search engine

For the user, it is desirable to

1. receive a large set of accurate matches
2. have the matches returned in order, where the order corresponds to some measure of “importance”

Ranking according to a measure of importance is the problem we now consider

The methodology developed to solve this problem by Google founders Larry Page and Sergey Brin is known as PageRank

To illustrate the idea, consider the following diagram
Imagine that this is a miniature version of the WWW, with

- each node representing a web page
- each arrow representing the existence of a link from one page to another

Now let’s think about which pages are likely to be important, in the sense of being valuable to a search engine user.

One possible criterion for the importance of a page is the number of inbound links — an indication of popularity.

By this measure, \( m \) and \( j \) are the most important pages, with 5 inbound links each.

However, what if the pages linking to \( m \), say, are not themselves important?

Thinking this way, it seems appropriate to weight the inbound nodes by relative importance.

The PageRank algorithm does precisely this.

A slightly simplified presentation that captures the basic idea is as follows:

Letting \( j \) be (the integer index of) a typical page and \( r_j \) be its ranking, we set

\[
  r_j = \sum_{i \in L_j} \frac{r_i}{\ell_i}
\]

where

- \( \ell_i \) is the total number of outbound links from \( i \)
- \( L_j \) is the set of all pages \( i \) such that \( i \) has a link to \( j \)

This is a measure of the number of inbound links, weighted by their own ranking (and normalized by \( 1/\ell_i \)).

There is, however, another interpretation, and it brings us back to Markov chains.

Let \( P \) be the matrix given by \( P(i, j) = 1\{i \to j\}/\ell_i \) where \( 1\{i \to j\} = 1 \) if \( i \) has a link to \( j \) and zero otherwise.

The matrix \( P \) is a stochastic matrix provided that each page has at least one link.
With this definition of $P$ we have

$$r_j = \sum_{i \in L_j} \frac{r_i}{\ell_i} = \sum_{i} 1\{i \to j\} \frac{r_i}{\ell_i} = \sum_{i} P(i,j)r_i$$

Writing $r$ for the row vector of rankings, this becomes $\mathbf{r} = \mathbf{r}P$

Hence $\mathbf{r}$ is the stationary distribution of the stochastic matrix $P$

Let’s think of $P(i, j)$ as the probability of “moving” from page $i$ to page $j$

The value $P(i, j)$ has the interpretation

- $P(i, j) = 1/k$ if $i$ has $k$ outbound links and $j$ is one of them
- $P(i, j) = 0$ if $i$ has no direct link to $j$

Thus, motion from page to page is that of a web surfer who moves from one page to another by randomly clicking on one of the links on that page.

Here “random” means that each link is selected with equal probability.

Since $\mathbf{r}$ is the stationary distribution of $P$, assuming that the uniform ergodicity condition is valid, we can interpret $r_j$ as the fraction of time that a (very persistent) random surfer spends at page $j$.

Your exercise is to apply this ranking algorithm to the graph pictured above and return the list of pages ordered by rank.

The data for this graph is in the `web_graph_data.txt` file — you can also view it here.

There is a total of 14 nodes (i.e., web pages), the first named $a$ and the last named $n$.

A typical line from the file has the form

`d -> h;`

This should be interpreted as meaning that there exists a link from $d$ to $h$.

To parse this file and extract the relevant information, you can use regular expressions.

The following code snippet provides a hint as to how you can go about this:

```python
In [21]: import re
   ...
   ...
   ...
   ...
   ...
   ...
```

```
Out[21]: ['x', 'y', 'z']
```

```
In [22]: re.findall('\\w', 'a ^\^ b &&\& $$ c')
```

```
Out[22]: ['a', 'b', 'c']
```

When you solve for the ranking, you will find that the highest ranked node is in fact $g$, while the lowest is $a$.

10.3 Exercise 3

In numerical work, it is sometimes convenient to replace a continuous model with a discrete one.

In particular, Markov chains are routinely generated as discrete approximations to AR(1) processes of the form

\[ y_{t+1} = \rho y_t + u_{t+1} \]

Here \( u_t \) is assumed to be IID and \( N(0, \sigma_u^2) \).

The variance of the stationary probability distribution of \( \{y_t\} \) is

\[ \sigma_y^2 := \frac{\sigma_u^2}{1 - \rho^2} \]

Tauchen’s method [4] is the most common method for approximating this continuous state process with a finite state Markov chain.

A routine for this already exists in QuantEcon.py but let’s write our own version as an exercise.

As a first step, we choose

- \( n \), the number of states for the discrete approximation
- \( m \), an integer that parameterizes the width of the state space

Next, we create a state space \( \{x_0, \ldots, x_{n-1}\} \subset \mathbb{R} \) and a stochastic \( n \times n \) matrix \( P \) such that

- \( x_0 = -m \sigma_y \)
- \( x_{n-1} = m \sigma_y \)
- \( x_{i+1} = x_i + s \) where \( s = (x_{n-1} - x_0)/(n - 1) \)

Let \( F \) be the cumulative distribution function of the normal distribution \( N(0, \sigma_u^2) \).

The values \( P(x_i, x_j) \) are computed to approximate the AR(1) process — omitting the derivation, the rules are as follows:

1. If \( j = 0 \), then set

\[ P(x_i, x_j) = P(x_i, x_0) = F(x_0 - \rho x_i + s/2) \]

1. If \( j = n - 1 \), then set

\[ P(x_i, x_j) = P(x_i, x_{n-1}) = 1 - F(x_{n-1} - \rho x_i - s/2) \]

1. Otherwise, set
The exercise is to write a function `approx_markov(rho, sigma_u, m=3, n=7)` that returns \( \{x_0, \ldots, x_{n-1}\} \subseteq \mathbb{R} \) and \( n \times n \) matrix \( P \) as described above.

- Even better, write a function that returns an instance of `QuantEcon.py`’s `MarkovChain` class

### 11 Solutions

#### 11.1 Exercise 1

Compute the fraction of time that the worker spends unemployed, and compare it to the stationary probability

```python
In [23]: import numpy as np
import matplotlib.pyplot as plt
from quantecon import MarkovChain

P(x_i, x_j) = F(x_j - \rho x_i + s/2) - F(x_j - \rho x_i - s/2)
```

```python
In [24]: \alpha = \beta = 0.1
N = 10000
p = \beta / (\alpha + \beta)

P = ((1 - \alpha, \alpha),
     (\beta, 1 - \beta))

P = np.array(P)
mc = MarkovChain(P)

fig, ax = plt.subplots(figsize=(9, 6))
ax.set_ylim(-0.25, 0.25)
ax.grid()
ax.hlines(0, 0, N, lw=2, alpha=0.6) # Horizontal line at zero
for x0, col in ((0, 'blue'), (1, 'green')):
    # == Generate time series for worker that starts at x0 == #
    X = mc.simulate(N, init=x0)
    # == Compute fraction of time spent unemployed, for each n == #
    X_bar = (X == 0).cumsum() / (1 + np.arange(N, dtype=float))
    # == Plot == #
    ax.fill_between(range(N), np.zeros(N), X_bar - p, color=col, alpha=0.1)
    ax.plot(X_bar - p, color=col, label=f'$X_0 = \{x0\}$')
    ax.plot(X_bar - p, 'k-', alpha=0.6) # Overlay in black--make lines clearer
ax.legend(loc='upper right')
plt.show()
```
11.2 Exercise 2

First, save the data into a file called \texttt{web\_graph\_data.txt} by executing the next cell

\begin{verbatim}
In [25]: %%file web_graph_data.txt
a -> d;
   a -> f;
b -> j;
b -> k;
b -> m;
c -> c;
c -> g;
c -> j;
c -> m;
d -> f;
d -> h;
d -> k;
e -> d;
e -> h;
e -> l;
f -> a;
f -> b;
f -> j;
f -> l;
g -> b;
g -> j;
h -> d;
h -> l;
h -> m;
i -> g;
i -> h;
i -> n;
j -> e;
j -> i;
j -> k;
k -> n;
l -> m;
\end{verbatim}
m -> g;
n -> c;
n -> j;
n -> m;

Writing web_graph_data.txt

In [26]: 

Return list of pages, ordered by rank 

```python
import numpy as np
from operator import itemgetter

infile = 'web_graph_data.txt'
alphabet = 'abcdefghijklmnopqrstuvwxyz'

n = 14 # Total number of web pages (nodes)

# == Create a matrix Q indicating existence of links == #
# * Q[i, j] = 1 if there is a link from i to j
# * Q[i, j] = 0 otherwise
Q = np.zeros((n, n), dtype=int)
f = open(infile, 'r')
edges = f.readlines()
f.close()
for edge in edges:
  from_node, to_node = re.findall(r'\w', edge)
i, j = alphabet.index(from_node), alphabet.index(to_node)
Q[i, j] = 1

# == Create the corresponding Markov matrix P == #
P = np.empty((n, n))
for i in range(n):
P[i, :] = Q[i, :].sum()
mc = MarkovChain(P)

# == Compute the stationary distribution r == #
r = mc.stationary_distributions[0]
ranked_pages = {alphabet[i]: r[i] for i in range(n)}

# == Print solution, sorted from highest to lowest rank == #
print('Rankings
***
for name, rank in sorted(ranked_pages.items(), key=itemgetter(1), reverse=1):
  print(f'{name}: {rank:.4}')

Rankings
***
g: 0.1607
j: 0.1594
m: 0.1195
n: 0.1088
k: 0.09106
b: 0.08326
e: 0.05312
i: 0.05312
c: 0.04834
h: 0.0456
l: 0.03282
d: 0.03056
f: 0.01164
a: 0.002911
```

11.3 Exercise 3

A solution from the QuantEcon.py library can be found here

Footnotes
Hint: First show that if $P$ and $Q$ are stochastic matrices then so is their product — to check the row sums, try post multiplying by a column vector of ones. Finally, argue that $P^n$ is a stochastic matrix using induction.
